Rethink Autoencoders: Robust Manifold Learning

Taihui Li 1  Rishabh Mehta 1  Zecheng Qian 1  Ju Sun 1

Abstract

PCA can be made robust to data corruption, i.e., robust PCA. What about the deep autoencoder, as a nonlinear generalization of PCA? This further motivates us to “reinvent” a factorization-based PCA as well as its nonlinear generalization. Focusing on sparse corruption, we model the sparsity structure explicitly using the $\ell_1$ norm to obtain various robust formulations. For linear data, robust factorization performs comparably to the seminal convex formulation of robust PCA, whereas robust autoencoders provably fail. For nonlinear data, we perform careful experimental evaluation of robust deep autoencoders and robust nonlinear factorization for corruption removal on natural images. Both schemes can remove a considerable level of sparse corruption and effectively reconstruct the clean images.

1. Introduction

From robust PCA to robust manifold learning. Despite its practical popularity, the classic PCA is well known to be sensitive to data corruption and outliers (Huber & Ronchetti, 2009). Over the last decade, a number of robust formulations of PCA (Candès et al., 2011; Chandrasekaran et al., 2011; Xu et al., 2012; Lerman et al., 2014) have been proposed, taking a common geometric view: finding a best-fit subspace to data that are contaminated by gross errors.

Can we do similar things for data lying on low-dimensional manifolds, which are often considered as natural generalizations of subspaces? For example, this is relevant for visual data: visual appearance of an object is determined by only few explanatory factors (e.g., pose, deformation, illumination, etc.) and its images lie near a low-dimensional manifold (Donoho & Grimes, 2005). On the other hand, cast shadows, occlusions, and defects in imaging sensors do not correspond to any explanatory factors of interest, but lead to structured erasure and irrelevant imputation of image pixels or parts—called corruptions, gross errors, and outliers. So we indeed have a low-dimensional manifold, or perhaps manifolds, and sparse corruptions and rare outliers.

Motivation: robustness against natural corruption & perturbation. Vision systems based on deep neural networks (DNNs) can be jeopardized by maliciously constructed small perturbations (Szegedy et al., 2013; Heaven, 2019; Miller et al., 2019). While this concerns mission-critical applications, it does not account for practical corruption and perturbation: e.g., salt-and-pepper noise, motion blurring, weather conditions, camera tilting, occlusions, that are not maliciously constructed and need not be small in any sense. Numerous recent works (Hosseini et al., 2017; Dodge & Karam, 2019; Geirhos et al., 2019; Hendrycks et al., 2019b; Hendrycks & Dietterich, 2019; Xie et al., 2019) have suggested DNN-based systems are also not robust against such corruption and perturbation.

Our contribution. In this paper, we focus on an unsupervised setting and show that robust recovery of nonlinear visual data subject to sparse corruption is possible. We model the sparsity structure explicitly and derive nonlinear generalizations of PCA and the robust variants—robust deep autoencoder and robust nonlinear factorization. We highlight the efficacy of nonlinear factorization, as an attractive simplification of autoencoders. In our experiments, the proposed robust models show great promise for performing robust visual manifold learning against sparse corruption.

2. Method

Let $x_1, \ldots, x_m \in \mathbb{R}^n$ be a set of zero-centered data points and write $X = [x_1, \ldots, x_m] \in \mathbb{R}^{n \times m}$. In this paper, we focus on additive sparse corruption, i.e. $\tilde{X} = X + C$, where $C$ is a sparse matrix containing very few nonzero entries. A crucial component in our formulations is to explicitly model the sparsity in $C$. While there are many choices, we use the classic $\ell_1$ norm $||\cdot||_1$ (Candès, 2014). Below, we always assume $p \leq n$.

2.1. PCA, Autoencoder, and Factorization

The classic PCA uses the top eigenspace of $XX^\top$, or equivalently, the top (left) singular-vector space of $X$ to fit the
When we observe the corrupted data $\hat{X}$, we want to explicitly account for the sparse corruption $C$. A convex relaxation proposed by a couple of breakthrough papers (Candès et al., 2011; Chandrasekaran et al., 2011) is

$$\min_{\hat{X}, C} \|X\|_2^2 + \lambda \|C\|_\ell_1 \quad \text{s.t.} \quad \hat{X} = X + C,$$

based on the observation that $X$ is low-rank if the data points it contains can be well approximated by a linear subspace. The norms $\|\cdot\|_2$ and $\|\cdot\|_\ell_1$ are used to promote the low-rankness and sparsity structures, respectively.

Here, we consider alternative formulations built directly on the autoencoder and factorization. This helps us to generalize easily to the manifold setting later. Now in autoencoder and factorization, we hope that $BAX$ and $BZ$ recover the low-rank part of $\hat{X}$, i.e., $\hat{X}$, so that the differences $\hat{X} - BAX$ and $\hat{X} - BZ$ both represent the sparse corruption $C$. Thus, it is natural to consider

$$\min_{A \in \mathbb{R}^{p \times n}, B \in \mathbb{R}^{n \times p}} \|\hat{X} - BAX\|_1 \quad \text{(robust autoencoder)},$$

$$\min_{B \in \mathbb{R}^{n \times p}, Z \in \mathbb{R}^{p \times m}} \|\hat{X} - BZ\|_1 \quad \text{(robust factorization)}.$$

Robust autoencoder will not work; we make a formal argument in Appendix B and direct simulation also confirms this. By contrast, robust factorization works in a regime even larger than the convex relaxation; again, see Appendix B. Robust factorization or its variants as an alternative formulation for robust PCA have been briefly discussed in (Li et al., 2018; Charisopoulos et al., 2019; Brooks et al., 2013).

2.3. Generalizations for Robust Manifold Learning

Now we move to the nonlinear world and assume the data lie on low-dimensional manifolds. The deep autoencoder is a simple generalization of the autoencoder into a nonlinear form:

$$\min_{W, V} \|X - g_V \circ f_W(X)\|_F^2 \quad \text{(deep autoencoder)}.$$

The idea is simply replacing encoder $A$ and decoder $B$ by nonlinear mappings $f_W$ and $g_V$, respectively. This is the exactly the autoencoder that people use for nonlinear dimension reduction (Hinton & Salakhutdinov, 2006), information retrieval (Salakhutdinov & Hinton, 2009), and outlier detection (Sakurada & Yairi, 2014)—successful training of deep autoencoders in Hinton & Salakhutdinov (2006) has spawned the current resurgence of DNNs.

The same idea also leads to a nonlinear generalization of factorization:

$$\min_{V, Z} \|X - g_V(Z)\|_F^2 \quad \text{(nonlinear factorization)}.$$

This formulation is much less popular than the deep autoencoder, although there exist few precursors (Tan & Mayrovouniotis, 1995; Fan & Cheng, 2018; Bojanowski et al., 2019; Park et al., 2019; Heckel & Hand, 2018). Arguably, it admits a more direct interpretation that deep autoencoders: it directly learns the explanatory factors $Z$ and the generative process modeled as a neural network $g_V$.

Inspired by the robust autoencoder and robust factorization, we propose natural robust extensions to deep autoencoder and nonlinear factorization:

$$\min_{W, V} \|\hat{X} - g_V \circ f_W(\hat{X})\|_1 \quad \text{(robust deep autoencoder, RDAE)},$$

$$\min_{V, Z} \|\hat{X} - g_V(Z)\|_1 \quad \text{(robust nonlinear factorization, RNLF)}.$$

In Section 2.2 we showed both theoretically and empirically that the robust autoencoder does not solve the robust PCA problem. Here, we nonetheless do not rule out RDAE, as the linear algebra argument is very specific to the linear case and things may change dramatically once we allow nonlinear mappings. In fact, as we shall see in the experiment (Section 3), RDAE and RNLF mostly perform comparably.

2.4. Generalization by Others

(Zhou & Paffenroth, 2017) proposes another robust version

"Rethink Autoencoders: Robust Manifold Learning"
of deep autoencoder as
\[
\min_{W, V, X} \| X - g_V \circ f_W(X) \|_F + \lambda \| \hat{X} - X \|_1,
\]
where they introduce an additional variable \( X \) to account for the clean data. In our RNLF, this is conveniently represented as \( g_V(Z) \) and hence our formulation is much neater. (Chalapathy et al., 2017) proposes a modification to the shallow autoencoder
\[
\min_{A, B, S} \| \hat{X} - A \sigma(B(\hat{X})) - S \|_F + \lambda_1(\|A\|_F^2 + \|B\|_F^2) + \lambda_2 \| S \|_1,
\]
where the \( \|A\|_F^2 + \|B\|_F^2 \) was inspired by nuclear norm as regularizer for low-rankness. Compared to both, our formulation is much cleaner.

3. Experiments

Figure 1. MNIST restored images by RDAE and RNLF for different severity levels of Impulse Noise.

Figure 2. MNIST restored images by RDAE and RNLF for different severity levels of Gaussian Noise.

3.1. Recovery: visual results

We verify the effectiveness of robust deep autoencoder (RDAE) and robust nonlinear factorization (RNLF) through preliminary experiments on a number of image benchmark datasets: MNIST (LeCun et al., 1998), Fashion-MNIST (Xiao et al., 2017), CIFAR10 and CIFAR100 (Krizhevsky et al., 2009). We simulate our corrupted images by applying Salt-and-Pepper Impulse Noise and Gaussian noise to the test data of these benchmark datasets with different severity levels, ranging from benign to severe corruptions. Different corruption severity levels and brief explanations are included in Table 2. In Fig. 1, Fig. 2, Fig. 3, and Fig. 4, we show randomly selected examples of restored images by our models along with the corresponding clean and corrupted images. It is clear that our models are able to recover images reasonable well, discarding the sparse noise present in them.

We implement RDAE and RNLF with the deep learning framework PyTorch 1.4. We build our neural network models using convolutional neural networks (CNNs), choose sigmoid activation \( \sigma(x) = \frac{1}{1+e^{-x}} \) or tanh activation \( \sigma(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \) in the output layer depending on the normalization used in image preprocessing, learn and update the network parameters and/or the latent codes using Adam (Kingma & Ba, 2014) for all network models. We also exploit the learning rate scheduler with a decay factor of 0.1 for every 100 epochs. The detailed network architecture along with the hyper-parameters are provided in Appendix C.

3.2. Recovery measured by classification accuracy

In this experiment, we evaluate the denoising effectiveness of RDAE and RNLF by feeding the restored images to DNN-based visual recognition systems. We use the recognition performances on clean and corrupted images as baseline references to measure how much our methods can help mit-
expansion, which is plausible and promising but seems un-
most exclusively hinged on data augmentation and model
et al., 2018; Lopes et al., 2019; Hendrycks et al., 2019a)
corruptions we consider here. The recent works (Geirhos
considered in these datasets are far broader than the sparse
tasks (Hendrycks et al., 2019b; Hendrycks & Dietterich,
average-case robustness in the supervised visual recognition
public datasets have been constructed to foster research on
Our focus here is on robustness for manifold learning, which
implicate the effects of corruption on classification. For each
corruption type, Impulse Noise and Gaussian Noise, we
conduct experiments on each individual corruption severity
and mixup corruption severity, respectively. Table 1 shows
that our methods can reconstruct both clean and corrupted
images reasonable well, without loss of any prime informa-
tion. As the corruption severity increases, the classification
accuracy of DNN-based models on the corrupted images
drop dramatically, while we can see graceful degradation
of the performance on the restored images by RDAE and
RNLF—which is always substantially better than the
corrupted images, even when the corruption is severe.

4. Related Work

Our focus here is on robustness for manifold learning, which
is intrinsically an unsupervised learning problem. Several
public datasets have been constructed to foster research on
average-case robustness in the supervised visual recognition
tasks (Hendrycks et al., 2019b; Hendrycks & Dieterich,
2019; Xie et al., 2019). The corruptions and perturbations
considered in these datasets are far broader than the sparse
corruptions we consider here. The recent works (Geirhos
et al., 2018; Lopes et al., 2019; Hendrycks et al., 2019a)
addressing the robustness issue on these datasets have
almost exclusively hinged on data augmentation and model
expansion, which is plausible and promising but seems un-
sustainable. Practical corruptions and perturbations tend to
much less amenable to low-dimensional models than the
informative visual contents themselves, raising the concern
if data augmentation can ultimately tame the curse of di-
mensionality. Here, instead of the data-driven approach, we
advocate a model-based approach to explicitly model the
structures in the corruptions and perturbations.

Our corruption removal task here may remind of denoising
autoencoders (Vincent et al., 2010). They are disparate, as
in training denoising autoencoders, clean data are required
and multiple iid noisy versions of the same data point are
seen—it is a supervised setting. Here, only one corrupted
version of each data point is seen and no clean data are
available—an unsupervised setting.

Nonlinear factorization can be traced back at least to (Tan
& Mayrovouniotis, 1995), and recently has been deployed for
deep nonlinear matrix factorization (Fan & Cheng, 2018),
generative models (Bojanowski et al., 2019), and 3D shape
representation (Park et al., 2019). Certain aspects of the
modeling and computational advantages have just started
to emerge. It is also closely related to the intriguing deep
generative priors (Ulyanov et al., 2018; Bora et al., 2017;
Heckel & Hand, 2018). We are the first to extend the idea
for robust representation learning.

Acknowledgments

The authors acknowledge the Minnesota Supercomputing
Institute (MSI) at the University of Minnesota for providing
resources that contributed to the research results reported
within this paper.

A. Factorization as PCA

**Theorem A.1.** Assume that $X \in \mathbb{R}^{n \times m}$ (with $m \geq n$) is full rank and that $X X^\top$ has distinct eigenvalues. Then, at any local minimizer of the optimization problem

$$\min_{B \in \mathbb{R}^{n \times p}, Z \in \mathbb{R}^{p \times m}} \|X - BZ\|_F^2, \ p \leq n,$$

(1)

$B$ spans the top rank-$p$ eigenspace of $X X^\top$. In fact, all these local minimizers are also global minimizers.

**Proof.** The first-order optimality condition is

$$B^\top X = B^\top B Z,$$

(2)

$$X Z^\top = B Z Z^\top.$$

(3)

By Eq. (2), at any first-order critical point,

$$Z = (B^\top B)^\dagger B^\top X + (I - B^\dagger B) L = B^\dagger X + (I - B^\dagger B) L$$

(4)

for arbitrary $L$’s with a compatible dimension, where $(\cdot)^\dagger$ denotes the matrix pseudoinverse. Thus, at any first-order critical point,

$$B Z = B B^\dagger X + B (I - B^\dagger B) L = B B^\dagger X,$$

(5)

where we have simplified the expression using $B = B B^\dagger B$. On the other hand, by Eq. (3), we have

$$X Z^\top B^\dagger = B Z Z^\top B^\dagger.$$

(6)

Substituting Eq. (5) into the last and write $\Sigma = X X^\top$, we obtain

$$\Sigma B B^\dagger = B B^\dagger \Sigma B B^\dagger,$$

(7)

where we have simplified the expression using that $BB^\dagger$ is symmetric. Since $BB^\dagger \Sigma B B^\dagger$ is symmetric, we conclude that

$$\Sigma B B^\dagger = BB^\dagger \Sigma.$$

(8)

Henceforth we will write $P$ to mean the orthoprojector, and $P_B = BB^\dagger$ simply means orthoprojector onto the column space of $B$. For any orthogonal matrix $U \in O_n$, it can be easily verified by expressing $B$ in its SVD form that

$$P_B = U P_{U^\top B} U^\top.$$

(9)

Substituting the last into Eq. (8) and write the eigendecomposition of $\Sigma$ as $\Sigma = U \Lambda U^\top$, we have that

$$U \Lambda U^\top U P_{U^\top B} U^\top = \Sigma B B^\dagger$$

$$= BB^\dagger \Lambda$$

(10)

$$= U P_{U^\top B} U^\top U \Lambda U^\top,$$

which implies

$$\Lambda P_{U^\top B} = P_{U^\top B} \Lambda.$$

(11)

Obviously, $P_{U^\top B}$ must be a diagonal matrix, since $\Lambda$ is diagonal with distinct values. Since it is an orthoprojector and hence $P_{U^\top B} = P_{U^\top B}^2$, we conclude that any diagonal element of $P_{U^\top B}$ is either 1 or 0.

So at any first order critical point, if $\text{rank}(B) = r$ (with $r \leq p$), there is an index set $J \subset \{1, \ldots, n\}$ so that

$$P_B = U P_{U^\top B} U^\top = U_J U_J^\top,$$

(12)

where $U_J$ consists of columns of $U$ indexed by $J$. Obviously, $\text{range}(B) = \text{range}(U_J)$. So $B$ can be written in the form

$$B = [U_J, 0_{n \times (p - r)}] C$$

(13)

for a certain invertible $C \in \mathbb{R}^{p \times p}$, implying that

$$B^\dagger = C^{-1} [U_J^\top, 0_{(p - r) \times n}].$$

(14)
Substituting this into Eq. (4), we obtain that
\[
Z = C^{-1} \begin{bmatrix} U_j^T \\ 0_{(p-r)\times n} \end{bmatrix} X \\
+ (I - C^{-1} \begin{bmatrix} U_j^T \\ 0_{(p-r)\times n} \end{bmatrix} [U_j, 0_{n\times (p-r)}] C) L \\
= C^{-1} \begin{bmatrix} U_j^T X \\ 0_{(p-r)\times n} \end{bmatrix} + C^{-1} \begin{bmatrix} 0 \\ I_{p-r} \end{bmatrix} CL \\
= C^{-1} \left[ U_j^T X \right]_{\text{last } p-r \text{ rows of } CL}.
\]

We now discuss two cases separately.

- \( r < p \). When \( r < p \), we can perturb \( L \) slightly (remember \( L \) can be arbitrary) to obtain a full-rank matrix \( \tilde{Z} \). It is easy to verify that \( BZ = B\tilde{Z} \). Now when \( \tilde{Z} \) is full-rank, \( f(B, \tilde{Z}) \) is strongly convex in \( B \). Hence we can find a \( \tilde{B} \) so that for all \( \tilde{B} = (1 - \varepsilon)B + \varepsilon\tilde{B} \) with \( \varepsilon \in (0, 1) \),

\[
f(\tilde{B}, \tilde{Z}) < f(B, \tilde{Z}) = f(B, Z). \tag{15}
\]

Since \( \varepsilon \) can also be made arbitrarily small and \( \tilde{B} \to B \) as \( \varepsilon \to 0 \), \((B, Z)\) is a saddle point.

- \( r = p \). In this case, we have

\[
B = U_j C \tag{16}
\]

\[
Z = C^{-1} U_j^T X \tag{17}
\]

for an index set \( J \subset \{1, \ldots, n\} \) with \(|J| = p \) and an invertible matrix \( C \in \mathbb{R}^{p \times p} \). There are \( \binom{n}{p} \) possible choices for \( J \), corresponding to \( \binom{n}{p} \) first-order critical points.

Next we show that when \( J \neq \{1, \ldots, p\} \), the corresponding critical point is not a local minimizer. First note that when \( B \) is full-rank, \( Z \) is uniquely determined by Eq. (2). So we have

\[
f(B, Z(B)) = \|X - BZ(B)\|_F^2 \\
= \|X - BB^T X\|_F^2 \\
= \|X - P_{B}X\|_F^2 \\
= \|X\|_F^2 - \langle U_j U_j^T, X \rangle \\
= \|X\|_F^2 - \langle I_j, A \rangle \\
= \|X\|_F^2 - \sum_{j \in J} \lambda_j.
\]

Now since \( J \neq \{1, \ldots, p\} \), there exists an index \( \ell \in \{1, \ldots, p\} \) but \( \ell \notin J \) and there also exists an index \( k \in J \) so that \( k \geq \ell \). Now consider an \( \varepsilon \)-perturbation to \( u_k \) (i.e., the \( k \)-th column in \( U \), where we assume that the columns in \( U \) are ordered corresponding to the descending order of the eigenvalues \( \lambda_i \)'s): \( \tilde{u}_k = (u_k + \varepsilon u_k)/\sqrt{1 + \varepsilon^2} \) and replace \( u_k \) in \( U_j \) by \( \tilde{u}_k \) to form \( \tilde{U}_j \). It is obvious we still have \( U_j^T \tilde{U}_j = I_j \). Now let \( \tilde{B} = U_j C \) and \( \tilde{Z} = C^{-1} U_j^T X \). The perturbed objective

\[
f(\tilde{B}, \tilde{Z}) = \|X\|_F^2 - \langle U_j \tilde{U}_j^T, X \rangle \\
= \|X\|_F^2 - \langle U_j \tilde{U}_j^T U_j, A \rangle \\
= \|X\|_F^2 - \sum_{j \in J, j \neq k} \lambda_j - \frac{1}{1 + \varepsilon^2} \lambda_k - \frac{\varepsilon^2}{1 + \varepsilon^2} \lambda_\ell. \tag{19}
\]

(20)

Since \( \lambda_k - \lambda_\ell < 0 \), we have that for all \( \varepsilon > 0 \)

\[
f(\tilde{B}, \tilde{Z}) < f(B, Z). \tag{22}
\]

Since \( \varepsilon \) can be arbitrarily small, \((B, Z)\) is a saddle point.

When \( J = \{1, \ldots, p\} \), the objective value is \( \|X\|_F^2 - \sum_{i=1}^{p} \lambda_i = \sum_{i=p+1}^{n} \lambda_i \). We know that \( BZ \) has a rank no larger than \( p \), and the best rank-\( p \) approximation to \( X \) leads to the lowest objective value, which is \( \sum_{i=p+1}^{n} \lambda_i \). So this case corresponds to a local minimizer which is also a global minimizer.

By the above argument, when \( J = \{1, \ldots, p\}, B = U_{[1, \ldots, p]} C \) for a certain invertible matrix \( C \). So \( B \) spans the top rank-\( p \) eigenspace of \( XX^T \), completing the proof.

**B. Robust Autoencoder vs. Robust Factorization**

We first argue that robust autoencoder will not work. For simplicity, we assume \( X \) is exactly rank-\( p \). Now if \( BA\tilde{X} \) were to recover the clean data \( X \), then \( \text{col}(BA\tilde{X}) = \text{col}(X) \) and \( \text{row}(BA\tilde{X}) = \text{row}(X) \), where \( \text{col}(\cdot) \) and \( \text{row}(\cdot) \) denote the column and row spaces, respectively. From \( \text{col}(BA\tilde{X}) = \text{col}(X) \) we know that \( B \) must be column full-rank, and so \( \text{row}(BA\tilde{X}) = \text{row}(A\tilde{X}) = \text{row}(X) \). The last equality implies that \( A \) must be row full-rank, and so \( \text{row}(\tilde{X}) = \text{row}(X) \), which is generally not possible for \( \tilde{X} = X + C \) with sparse but substantial \( C \). Direct simulation in Fig. 5 confirms this argument and robust autoencoder almost always fails. By contrast, robust factorization works in a larger regime than the convex relaxation,
and continues to work reasonably even if we over-specify the rank $p$.

C. Network Architecture

Table 3. Robust Deep Autoencoder network architecture for MNIST and Fashion-MNIST datasets.
